Kaposi’s sarcoma (KS) is a rare type of visceral and soft tissue sarcoma related to human herpes virus (HHV)-8 characterized by the proliferation of spindle shaped cells, mainly of vascular origin. Clinically, KS is a slowly progressing malign lesion manifesting with cutaneous lesions with or without involvement of internal visceral organs and/or lymph nodes. It is classified clinicopathologically into four subgroups based on epidemiological data which are classical, endemic (African type), epidemic (AIDS-related), and iatrogenic (transplantation-related) KS. The type observed in the organ transplant recipients is known as a type that is considered to be related to immunosuppression and may regress after the discontinuation of the therapy or may show an aggressive and multifocal course compared to classical type. Both sporadic and opportunistic forms of KS are associated with the presence of the HHV-8 genome in the neoplastic cells. Although its incidence varies across different types, the most common presentation is purple, blue, red or dark brown, black macula, papule, plaque and nodular skin lesions and accompanying lymphedema, especially in the lower extremities. Systemic therapy may be considered in the patients with symptomatic visceral and mucosal involvement. For systemic therapy, in addition to the drugs such as anthracyclines, vinca alkaloids, bleomycin, oral etoposide and gemcitabine, taxanes have also being used during recent years for their antiangiogenic effects. Moreover, several studies have shown that paclitaxel monotherapy is a successful second-line treatment for both AIDS-associated KS and KS in a therapeutically immunosuppressed patient. Additionally, for patients with epidemic or iatrogenic KS, the most effective treatment requires correcting the underlying immunodeficiency.

In this report, we present a patient with disseminated visceral KS after liver transplant.
transplantation who has showed a dramatic response to Paclitaxel therapy.

Case Report

A seven year-old girl with chronic liver failure secondary to progressive familial intrahepatic cholestasis type III (PFIC III) was transplanted with a left lateral segment from her mother. The patient was third of four children from a first degree-cousin marriage. Her older brother and cousin were also diagnosed with PFIC III, and both were liver transplanted. According to current immunosuppression protocol, she received IV methylprednisolone at the dose of 10 mg/kg during surgery and the dose was decreased to 2 mg/kg/day at the end of the first week. Then, steroid was tapered to the dose of 0.5 mg/kg/day in the post-transplant first month and withdrawn at the end of the post-transplant third month. She was given tacrolimus during the post-transplant period. One year after transplantation, she was presented with ascites. On physical examination of the oral cavity, there were 2x3 cm brown-blue-red nodule posterior of lower incisors (Fig. 1). Complete blood count revealed pancytopenia. Coagulation profile together with blood biochemistry was unremarkable. Serological tests for CMV and EBV IgM, CMV antigen testing, PCR for CMV and EBV were all negative. In addition, HIV antigens were negative. Abdominal CT revealed multiple enlarged mesenteric lymph nodes. Endoscopic examination revealed multiple polypoid brown-blue-red lesions on esophagus, stomach and duodenum. Multiple biopsies from said lesions revealed an infiltration of neoplastic cells with round-oval nuclei and moderate-sized eosinophilic cytoplasm, and red blood cells among them. In immunohistochemical assessment, the neoplastic cells displayed CD34, CD31 (Fig. 2a) and HHV-8 immunoreactivity (Fig. 2b). The histopathological examination of biopsy was consistent with HHV-8 related KS. Tacrolimus was switched to sirolimus at a dose of 2 mg/m² to keep the serum levels around 5 ng/ml. In due course, no regression of the lesions was observed. Paclitaxel therapy at a dose of 100 mg/m² per three weeks was started. Informed consent was received from the family. Oral lesions regressed rapidly following first cycle; after four cycles of paclitaxel, all lesions were resolved completely (Fig. 3). The gastrointestinal endoscopic examination was macroscopically absent of any kaposiform lesion and histopathology of multiple biopsies was completely normal. Paclitaxel was tolerated well by the patient. Bone marrow suppression which developed during therapy was easily controlled by supportive therapy without any clinical manifestation. Now the patient is free of disease for at least 18 months and completely healthy with good hepatic graft function.

Fig. 3. After four cycles of paclitaxel therapy, the lesion in the oral cavity regressed totally.
Discussion

Because of the rarity of pediatric KS, there is a paucity of literature on treatment and outcome stratification with most treatment modality options extracted from literature of adults treated for KS. To date, there is no established consensus group therapeutic guidelines for the treatment of all four forms of pediatric KS.

Strong correlation between the immunosuppressive status of the patient and the development of KS is very well demonstrated, and it is now a major and increasing problem in organ transplant recipients.\(^6\) Unlike adult recipients, KS in pediatric organ transplantation is quite rare and mainly observed in renal allograft recipients.\(^6\) It is reported rarely after liver transplantation in children.\(^7,8\) Compared with renal transplant recipients, visceral involvement is more frequent among liver transplant recipients.\(^9\) So, the tendency to dissemination and systemic nature of KS in liver transplant recipients is considered to be responsible for shorter survival than those who have undergone renal transplantation.\(^10\)

Reduction or discontinuation of immunosuppressive treatment is the first step in the treatment of iatrogenic KS and it has been associated with the disappearance of lesions.\(^11,12\)
In addition, there is evidence that patients with iatrogenic KS have had tumor regression when immunosuppression has been switched to sirolimus, a mammalian target of rapamycin (mTOR) inhibitor sharing both immunosuppressive and anti-neoplastic effects. Unlike other immunosuppressants, sirolimus has potent antitumor activity in vitro and in vivo. Sirolimus having antiproliferative and antitumor effect has been increasingly reported in the management of the disease. In the presented case, tacrolimus has been withdrawn and sirolimus has been started. However, lesions have remained unaltered and chemotherapy has commenced.

Therapeutic options for KS are based upon disease stage, progression pattern and distribution, clinical type, and immune status. For KS patients with more widely disseminated, progressive or symptomatic disease, systemic therapy with cytotoxic chemotherapy is generally warranted. The present case was not eligible for local therapy because she had multiple visceral and mucosal lesions. Several single agent therapies have been reported to be active in all subtypes of KS (vincristine, vinorelbine, etoposide, Adriamycin, liposomal doxorubicin, epirubicin, bleomycin, docetaxel and paclitaxel) with an overall response rate ranging from 30 to 70%, although most of them have been partial responses.

Taxanes (paclitaxel and docetaxel) are now promising agents in the treatment of KS with tolerable side effects. They have potent antiangiogenic activities, which may explain their efficacy on Kaposi lesions. Paclitaxel is a drug affecting the microtubules and cellular vital processes in nonmitotic phases of the cell cycle and it inhibits the growth of proliferating tumors either rapidly or slowly. The efficacy of paclitaxel given as second-line or third-line therapy has been evaluated well in association with highly active antiretroviral therapy in patients with AIDS-related KS. Recently, some articles about its efficacy in the treatment of classical, endemic and post-transplantation types of KS have also been published. Patel et al. have demonstrated prompt and durable response in two renal transplant recipients.

Limited cases of pediatric iatrogenic KS have shown promising response to mTOR inhibitor sirolimus, and paclitaxel chemotherapy. Based on these data, because of promising results and tolerable side effects, we decided to start paclitaxel monotherapy as first line treatment. We continued to give sirolimus after the completion of chemotherapy regimen as maintenance, because it is an effective agent in both treatments of KS and prevention of organ rejection.

Pediatric patients with post-liver transplant who develop KS may face a dismal prognosis. Celtik et al. describe a 15-month-old child who underwent liver transplant with subsequent pancytopenia, lymphadenopathy, edema, and subconjunctival bleeding. A cervical lymph node biopsy confirmed the diagnosis of disseminated KS. The first chemotherapy choice was weekly vinblastine, but the child was unresponsive. Second-line chemotherapy with, actinomycin D and cyclophosphamide was not effective. Then durable response was ensured by paclitaxel. Similar findings of multi-visceral KS after pediatric liver transplant have also been described in Mexico, France, and Turkey; many with fatal outcomes. Anthracyclines are another treatment option but limited effects with cardiotoxic side effects restrict its preference. When evaluating child and adult data on post-transplant KS, cytotoxic chemotherapy does not appear to be very effective. In addition, serious side effects associated with these treatments have been observed. Recently, efficacy of paclitaxel in post-transplant type KS has been published. Paclitaxel was the first chemotherapy option in pediatric post-transplant KS. Paclitaxel-related side effects were also much fewer than other chemotherapeutic agents.

In the present case, KS regressed completely after four cycles of Paclitaxel and remained in remission for 18 months.
In conclusion, KS continues to cause significant morbidity and mortality worldwide in both pediatric and adult populations. Our experience suggests that paclitaxel is a promising and effective first line option for treatment of iatrogenic KS with tolerable side effects and sustained response. Further studies are required to standardize the paclitaxel treatment schedule and dosage in the disseminated iatrogenic type of KS.
