Neonatal Intensive Care Units (NICUs) are crucial for supporting vital functions and decreasing the rates of neonatal morbidity and mortality. On the other hand, the special care procedures in the NICU have adverse effects on the short and long-term development of infants. The NICU’s environment consists of many stressors for preterm infants, who are subjected to excessive sensory stimuli such as loud sounds, bright lights, and painful medical procedures. These excessive stimuli during a key period in the brain’s development might affect the physiological responses of infants and cause negative changes in motor, neurological, and sensory development. The reason for this is a lack of inhibitory control for selecting, controlling, and processing sensory stimuli in the developing premature brain. Therefore, the relationship between the NICU and premature birth might set off a chain of adverse events that could lead to learning difficulties and sensory and motor dysfunction.
Sensory processing is the innate ability to interpret and process sensory inputs and to produce the most appropriate response to the environment. Inadequate sensory processing may contribute to a sensory processing disorder. This disorder involves difficulties in processing and transforming the sensory information used for the regulation of physiological, motor, and emotional or attentional responses in the organization of behavior. This may result in excessive or insufficient responses to sensory stimuli in the child.

Atypical sensory behaviors affect a child’s participation in daily living activities, which may cause a delay in developmental milestones. Therefore, processing sensory inputs correctly is essential in normal neurodevelopment. Particularly, impairments in the inputs of the vestibular, proprioceptive, and tactile sensory systems may cause problems in producing adaptive behavior, movement coordination, and the development of postural control and motor development. Sensory processing disorder affects 39 to 52% of preterm infants, and infants born before 32 weeks of gestation are at greater risk.

Most of the relevant research has focused on the cognitive development outcomes of preterm infants. Only a few studies have investigated the relationship between the motor and sensory development of preterm infants in the first year of life, and the available results are conflicting. Celik et al. indicated that there is a significant association of gross motor function with sensory processing among infants born prematurely at corrected ages of 10-12 months, whereas Cabral et al. could not find any relationship between motor function and sensory processing in premature infants at 4-6 months old.

In a recent study, de Paula Machado et al. investigated the relationship between motor development, cognitive development, and sensory processing at the age of 12 months. They indicated that early birth adversely affected sensory processing, and ocular-motor control in sensory processing was positively correlated with motor development. However, they only provide insight into sensory processing and prematurity at the age of 12 months. The main possible reasons for these inconsistent results are the cross-sectional design of the studies and the heterogeneity of the sample groups. Myelination begins in the 2nd trimester continues during the first year of life. Therefore, observing motor and sensory development prospectively is clinically important for determining difficulties in sensory processing and motor delay in the first year of life, which is crucial for referral to necessary early interventions.

There is quite limited research on sensory processing disorder during the first year of life in infants born preterm. Furthermore, there is an essential need to focus on this subject in prospective studies. Thus, the aim of this study was to determine the association of sensory processing with motor development among infants born very preterm with developmental delay and very preterm infants who had typical development. We hypothesized that preterm infants with developmental delay would have poorer sensory processing and motor performance than preterm infants with typical development. We also hypothesized there is a relationship between improved fine and gross motor outcomes and better sensory processing.

Material and Methods

Approval for this prospective study was obtained from the Ethics Committee of the University of Health Sciences, Non-Interventional Clinical Researches Ethics Board Project No: 18/250). The families included were informed about the study, and the necessary permission was obtained with signed informed consent forms. The Declaration of Helsinki was applied in the study process.

Participants

We recruited 78 very preterm infants who were treated at a university hospital in the
department of pediatric neurology between October 2018 and March 2019. The inclusion criteria for infants in the preterm delayed group included (1) gestational age of 32 weeks or less and a current corrected age of 8 months; (2) having spent at least 15 days in the NICU; and (3) a diagnosis of developmental delay by a pediatric neurologist and child and adolescent psychiatrist according to clinical evaluation and the Denver Developmental Screening Test-II. The inclusion criteria for the preterm comparison group were (1) gestational age of 32 weeks or less and a current corrected age of 8 months; (2) having spent at least 15 days in the NICU; and (3) normal motor development based on the Denver Developmental Screening Test-II. Infants were excluded from the study if they had any congenital abnormalities, genetic syndromes, musculoskeletal disorders, or hearing or visual impairment.

Of the 78 participants, 36 were assigned to the preterm delayed group (preterm infants with developmental delay), and 42 were assigned to the preterm comparison group (preterm infants with normal development), after dropouts which have been shown in Fig. 1, 33 infants in the preterm delayed group and 28 infants in the preterm comparison group completed all the assessments.

**Procedures**

Approximately two hours after feeding, standardized assessments were performed on a large mattress on the floor or on a table with the infant in a sitting position on the mother’s lap. The infants did not take any medication that would interfere with the assessment. The Neuro-sensory Motor Developmental Assessment (NSMDA) and the Test of Sensory Functions in Infants (TSFI) were used for the evaluations, which each took approximately 20 minutes. The NSMDA and TSFI tests were applied to infants at corrected ages of 8 and 12 months. The NSMDA was applied by the first author, who had 10 years of experience in pediatric rehabilitation. The TSFI was applied by the second author, who had nine years of experience in pediatric rehabilitation.

**Neuro-Sensory Motor Developmental Assessment (NSMDA)**

The NSMDA consists of six sections that evaluate the movement function of children at 1 month to 6 years of age. It is a criterion-referenced test, and the categories evaluated are age-appropriate: (1) gross motor function, (2) fine motor function, (3) neurological status, (4) infant patterns of movement, (5) posture and balance, and (6) sensory-motor function. The scores of these six areas are summed to calculate a neurosensory motor developmental score. Development in each section is given points ranging from 1 (within normal limits) to 5 (no independent function). The scores of each section are summed to obtain functional grade scores for the motor performance classification of infants.

Total functional grade scores of 6–8 on the NSMDA were classified as normal motor function, scores of 9-11 indicated minimal motor problems, scores of 12-13 indicated mild motor problems, scores of 14-19 indicated moderate motor problems, scores of 20-25 indicated severe motor dysfunction, and scores of >25 indicated profound motor dysfunction. The biggest advantage of the NSMDA is its ability to differentiate between normal motor function and minimal, mild, moderate, or severe motor dysfunction. The psychometric properties of the NSMDA have been identified for preterm and extremely low-birth-weight infants.

**Test of Sensory Functions in Infants (TSFI)**

The TSFI assesses the disturbances of sensorimotor integration that have a risk of occurrence in children aged 4 - 18 months. The TSFI consists of five subtests and 24 items that assess the functioning of the basic senses by observing the following features: sensitivity to deep pressure, the level of adaptive motor functions, visual-tactile coordination, control of eye movements, and the level of integration.
Fig. 1. Follow-up diagram.
of vestibular information. The range of the total score is 0 to 49, and higher scores show improved sensory processing.

The TSFI has cutoff values of four different age groups for both the subtests and the total score according to norm-referenced values of North American infants with typical development. Based on the cutoff values, sensory processing skills are evaluated as normal, risky, or abnormal.\(^{31}\) Worldwide, the sensory processing of infants is usually assessed with the TSFI. It has commonly been used to determine the difficulties in sensory processing in preterm infants by Turkish researchers,\(^{21}\) but a validation study for the Turkish population has not been performed yet.\(^{32}\)

**Statistical analysis**

Statistical analyses were performed using the software SPSS version 21 for macOS (IBM SPSS Statistics; IBM Corporation, Armonk, NY, USA). The number of individuals needed in the study was determined to be 30 according to a power analysis using \(\alpha=0.05\) and \(\beta=0.20\) (for 80% power).\(^{21}\) The conformity of the variables to a normal distribution was determined by the Kolmogorov-Smirnov test along with histogram and box plots.

Descriptive statistics of the data were calculated with the mean and standard deviation. Mann-Whitney’s U-test was used to describe the differences between groups at the ages of 8 and 12 months in the NSMDA sub-parameters and TSFI results. The relationship between the NSMDA and TSFI results of the preterm infants was analyzed with the Spearman correlation test. In the evaluation of the relationship, the correlation coefficients were classified as follows: 0 – 0.24: weak, 0.25 – 0.49: moderate, 0.50 – 0.74: strong, 0.75 – 1.00: very strong.\(^{33}\) \(p<0.05\) was considered as statistically significant.

**Results**

The characteristics of the preterm infants are presented in Table I. There were no statistical differences between the groups. Baseline data showed that each group was well matched, including gestational age, birth weight, gender, maternal age, days in the neonatal care unit, etc.

Table II shows the median NSMDA and TSFI scores of the preterm infants and the differences at corrected ages of 8 and 12 months for each group. Compared to the average normal scores of the NSMDA subdomains, the preterm infants in the preterm delayed group showed decreases

*Mann-Whitney’s U-test, * p<0.05, NSMDA: neurosensory motor developmental assessment, TSFI: test of infant sensory profile scores

of 50% in gross motor scores (30 versus 15), 33.3% in fine motor scores (15 versus 10), 66.6% in tactile scores (12 versus 4), 50% in ocular scores (12 versus 6), and 50% in vestibular scores (12 versus 6) at 8 months. At 12 months, the preterm delayed group’s subdomain scores
showed decreases of 29.1% in gross motor scores (24 versus 17), 26.6% in fine motor scores (15 versus 11), 33.3% in tactile scores (12 versus 8), 33.3% in ocular scores, and 33.3% in vestibular scores (12 versus 8) compared to the average normal scores.

In the preterm comparison group, the median scores of the NSMDA subdomains were in the normal range at 8 and 12 months. The median functional level indicated moderate motor problems for the preterm delayed group and normal motor function for the preterm comparison group at the ages of 8 and 12 months. The median TSFI total and subdomains scores were classified as risky-abnormal for the preterm delayed group and normal for the preterm comparison group at 8 and 12 months. There were also significant differences in the NSMDA subdomains and functional levels, TSFI subdomains, and the total TSFI score between the preterm delayed and preterm comparison groups at corrected ages of 8 and 12 months (p<0.001).

According to the NSMDA functional level score, 13 preterm infants were classified as having minimal-mild motor problems, and 20 had moderate to profound motor problems at the corrected age of 8 months. Based on the total scores of TSFI, 7 infants were in the risky group, and 27 were in the abnormal group at 8 months. At the corrected age of 12 months, the NSMDA indicated that 14 preterm infants were classified as having minimal-mild motor problems, and 19 had moderate to profound motor problems. Based on the total scores of TSFI, 8 infants were in the risky group, and 26 were in the abnormal group. Table III shows the classification of motor and sensory levels of the infants born very preterm.

There was a very strong positive correlation between the gross and fine motor scores of the NSMDA and the NSMDA sensory subdomains (tactile, vestibular, and ocular). Furthermore, there were very strong positive correlations between gross and fine motor scores of the NSMDA and the total and subdomain scores of the TSFI. There were very strong negative correlations between the functional level according to the NSMDA, the NSMDA subdomains, and the TSFI’s total and subdomain scores (p<0.001; Table IV, Fig. 2).

**Discussion**

This prospective study investigated the correlation of motor development with sensory processing at the ages of 8 and 12 months among infants born very preterm. The results show that very preterm infants with developmental delay were in the risky-abnormal group of sensory processing and had moderate motor problems in motor development. In addition, there were very strong positive correlations between gross and fine motor function development and sensory processing at the ages of 8 and 12 months in infants born very preterm. Particularly, there were very strong negative correlations between sensory processing and motor performance.

Research indicates that very preterm infants have a higher risk of neurosensory motor disorders than their term-born peers.34 Pin et

NSMDA: neurosensory motor developmental assessment, TSFI: test of infant sensory profile scores
al.\textsuperscript{35} showed that at 8 months, preterm infants exhibit similar movements to their term-born peers in prone and supine positions. However, there were significant differences between them in motor performance in sitting and standing postures, which require more muscle activation and motor control against gravity.

Olsen et al.\textsuperscript{36} investigated the neurodevelopmental results of 137 preterm infants at the age of 12 months who were born before 30 weeks of gestation. They demonstrated that the functional level of 76.6\% of preterm infants was classified as mild to severe motor dysfunction according to the NSMDA.

Similarly, the gross and fine motor scores of preterm infants with developmental delay in our study were below the average normal score. In addition, 33\% of preterm infants in our study were classified as having minimal to profound motor dysfunction according to the functional level. Preterm infants have a higher risk for motor problems, so a multidisciplinary team approach in the NICU is crucial to detect and follow-up these preterm infants with motor delay and educate the family in an early period, especially in developing countries.

During the first year of life, the accuracy of neuromotor assessments is conflicting because motor development is not only fast and comprehensive but is also influenced by biological, environmental, and social factors. Burns et al.\textsuperscript{26} indicated that the 8th month is the best evaluation month to predict normal or abnormal motor development in infants. Delays in gross and fine motor development could thus occur with increasing age. Therefore, in this prospective study, preterm infants were first assessed at 8 months to obtain information about motor performance and sensory processing about infants born very preterm.

Preterm infants are at high risk for sensory development from exposure to adverse sensory feedback, such as long-term intubation, heel-lance procedures, and intense sounds and lights in the NICU, as opposed to the safe environment of the uterus. Ryckman et al.\textsuperscript{3} investigated sensory processing disorder in preterm infants born at 30 weeks or earlier when they had reached the age of 4-6 years. They demonstrated that 50\% of the children had sensory processing disorder.

\caption{Table IV. Relationship between NSMDA and TSFI scores.}
\end{table}
Fig. 2. (a, b, c) Relationship between gross motor, fine motor, and total TSFI scores at 8 months, (d, e, f) Relationship between gross motor, fine motor, and total TSFI scores at 12 months.
Similarly, Chorna et al.\textsuperscript{22} found abnormal sensory reactivity at 12 months of age in 82% of infants born with weights of 1500 grams or less. Cabral et al.\textsuperscript{8} showed significant differences in tactile deep pressure perception between term and preterm infants born at 37 weeks of gestation or earlier who stayed in the NICU for at least one day. Celik et al.\textsuperscript{21} showed that there was a risk of sensory development issues in 60% of infants at the ages of 10-12 months who were born at 37 weeks or earlier and stayed in the NICU for at least 15 days.

The current study investigated the sensory processing of very preterm infants at the ages of 8 and 12 months. Similar to the literature, the TSFI indicated that infants born very preterm in this study had a higher risk in terms of oculomotor control, response to tactile deep pressure, visual-tactile integration, adaptive motor functions, and response to vestibular stimuli at the ages of 8 and 12 months. Furthermore, 44.3% of them at 8 months and 42.6% of them at 12 months had abnormal sensory processing. Findings from a recent study by de Paula Machado et al.\textsuperscript{4} support our results in that there was a negative correlation between premature birth and sensory processing.

It is not surprising to observe the adverse effects of daily stressors in the NICU among preterm infants. NICU professionals should be aware of the increasing risk of sensory processing difficulties in preterm infants. In addition, neonatologists could improve strategies with physiotherapists and occupational therapists to prevent sensory processing problems during the first year of life, when cerebral plasticity is greater.

A few studies have investigated the relationship between motor development and sensory processing. Cabral et al.\textsuperscript{8} indicated that 53% of preterm infants at the ages of 4-18 months had a risk of gross motor developmental delays. However, they did not show a statistically significant association between motor function development and sensory processing. A possible reason for this might be that they included preterm infants born at 37 weeks or earlier who stayed in the NICU for at least one day. Chorna et al.\textsuperscript{22} showed that preterm infants who had abnormal reactivity at 12 months also had worse motor and language developmental scores than preterm infants who had normal reactivity at 12 months. Celik et al.\textsuperscript{21} did a cross-sectional study that demonstrated a strong, significant, positive relationship between gross motor function and sensory processing in preterm infants at the age of 10-12 months.

In contrast to the literature, the present study prospectively investigated the relationship of motor performance with sensory processing in very preterm infants with developmental delay, along with very preterm infants with typical development at the ages of 8 and 12 months. As a result, we found that there were very strong positive correlations between the TSFI’s total and subdomain scores and the NSMDA’s fine and gross motor scores. Furthermore, there were very strong negative correlations between the TSFI’s total and subdomain scores and functional levels. Recent findings add support to our results that improved sensory processing is related to better motor development at the age of 12 months among infants born preterm and full term.\textsuperscript{4} These results reflect that sensory processing and motor function development are inseparable parts of infant development. In the early rehabilitation process, therapists should take development in its entirety into consideration.

No previous study has investigated the relationship between fine motor development and sensory processing. Our findings showed that there were very strong positive correlations between tactile, ocular, and vestibular processing and fine motor development. Chorna et al.\textsuperscript{22} showed that 21% of preterm infants had a risk of vestibular issues, 49% had a risk of tactile issues, and 33% had a risk of ocular processing issues, which was supported by our results. Similarly, Celik et al.\textsuperscript{21} found a moderate correlation between vestibular and ocular processing and motor development. In light of these findings, rehabilitation approaches that are aimed at
improving fine motor development should consist of supporting vestibular, ocular, and tactile sensory processing in preterm infants.

There were some limitations to this study. One of them is that no term control group was included. Furthermore, there was no long-term follow-up of the neurodevelopmental outcomes in this cohort. Future studies should determine the association of motor function development with sensory processing. Long-term follow-up of preterm infants and comparison to term infants should also be conducted.

Preterm infants had a high risk of motor developmental delays and sensory processing disorder. There were very strong relationships between motor function development and sensory processing. The effects of sensory-based early intervention programs for preterm infants should be researched.
